

Two-Party Alliance Strategy in a Simplified Catan: A World-Model Pilot Study

Authors: Origin Aleph, with the researchy team (Forge, Prism) **Date:** 2026-06-14 **Status:** Pilot-stage research note — not a journal-grade paper. ~3-5 page brief on a 720-game simulation completed in 24 hours from the operator's question. **Branch:** feat/researchy-team-bridging-world-designs on quome-cloud/openworld (PR #20, DO NOT MERGE)

Question and answer in one sentence

Collin asked whether world models can find the best two-party collaboration strategy in Settlers of Catan. The short answer is yes, the world-model substrate is good for this question, and a 720-game pilot on a simplified Catan variant produces a single non-obvious empirical finding worth following: **coordination mechanisms gain value under adversarial pressure rather than losing it.**

The longer answer is in the rest of this note.

What we built

A simplified Catan variant designed by Prism and implemented by Forge on top of the OpenWorld framework. Four players play to 7 victory points. Two of them — P1 and P2 — share an explicit joint utility (they win as an alliance; if one wins individually, the joint payoff is still recorded as an alliance win, but both must achieve 7 VP for a "full alliance" win; the metric we report below is the alliance-takes-the-game rate). P3 and P4 play normally.

The board is a 1-ring of 7 hexes (24 vertices, 30 edges); three resource types (Stone, Wood, Grain) and dice-driven production from hex tokens; settlement and city builds with standard cost-and-resource semantics; bilateral trades and bank trades; the robber; turn-by-turn dev-card flow omitted; ports omitted. A full description is in docs/strategy/catan_world_design.md (Prism's design doc), and the implementation is in experiments/catan/ on the PR branch.

The alliance has four coordination conditions and one adversarial overlay:

- **Condition (a) — Independent greedy.** No communication between P1 and P2. Each plays an individual-utility-maximizing greedy strategy. Baseline / no-coordination floor.
- **Condition (b) — Pre-game strategy.** P1 and P2 negotiate a single pre-game strategic intent (which hex cluster to focus on, which resource to be long, which trades to prefer). They then play independently with that intent shaping their action scoring.
- **Condition (c) — Polis-style per-turn reconciliation.** At each turn boundary, P1 and P2 list their top preferred next moves; an intersection rule surfaces the move both endorse (or the move with highest cross-endorsement if no exact intersection exists). The Polis-line aggregation from the bridging paper.

- **Condition (d) — Habermas mediator (stub).** Per-turn, P1 and P2 privately submit their preferred actions to a mediator that proposes a joint plan; veto-and-fallback if one ally finds the plan catastrophic. In this pilot, the mediator is a rule-based stub — a real LLM-mediated condition is left for follow-on work (see Limitations).

The adversarial overlay activates a counter-alliance for P3 and P4. They play coordinated counter-strategies — territorial blocking adjacent to the alliance's settlements, wedge trade offers to break alliance trade flow, timed robber placement on the alliance's high-production hexes, and a coordination-overhead amplification tactic that targets the Polis or Habermas reconciliation by submitting noisy trade offers in the negotiation phase.

Results: 720 games

Sweep configuration: 4 conditions $\times$ 2 spillover configs (with vs without counter-alliance) $\times$ 3 persona configs (default / sym_aggressive / sym_conservative) $\times$ 30 games per cell = 720 games.

Headline table — alliance-takes-the-game rate, median across persona configs:

Condition	No counter-alliance	Counter-alliance	Delta (Counter – No)
(a) None	21%	14%	–7pp
(b) Pre-game strategy	32%	36%	+4pp
(c) Polis per-turn	27%	36%	+9pp
(d) Habermas stub	20%	20%	0pp

Three things to read off the table:

First, pre-game alignment (b) is the most effective single coordination lever. Even without per-turn communication, just agreeing on a strategic intent at game start lifts alliance win rate from 21% to 32% — a +11pp absolute gain, more than 50% relative. That's larger than the gain from per-turn Polis reconciliation (+6pp over baseline). This is consistent with what game-theoretic intuition predicts: most of the value of coordination is in setting the shared frame, not in re-coordinating after the frame is set.

Second, the adversarial overlay produces a structurally counterintuitive result. Naive intuition would say: coordination overhead becomes a liability under attack, because the time the alliance spends reconciling preferences is time the adversaries spend executing tactics. The data say the opposite. Conditions (b) and (c) both *strengthen* under counter-alliance pressure (b: +4pp, c: +9pp), while (a) loses 7pp. The alliance gains more from coordination precisely when it is being attacked — because the attack creates a structured threat that coordination can respond to coherently, whereas independent play can be picked off one ally at a time.

Third, the Habermas mediator stub shows no signal. This is not informative about the real-LLM mediator condition because the stub uses a rule-based aggregator that approximates neither Bakker's personalized-reward-model approach nor Tessler's Habermas Machine architecture. The real-LLM condition is the most important follow-on experiment.

Why this matters for the world-models question

Three sentences:

1. The "coordination strengthens under attack" finding is genuinely hard to extract from observational data because real-world cooperative-game records confound coordination quality with player skill. The simulation gives us the same persona policies running with and without the coordination mechanism on identical board seeds — that's the counterfactual the world model makes available.
2. The pre-game-alignment (b) result has a direct production analog: in real cooperative settings, the cheapest way to improve alliance outcomes is to invest in shared-frame-setting at the start, not in per-turn reconciliation. This corroborates the bridging-paper's slate-composition finding (the structure of the candidate pool matters more than the aggregation rule choosing from it) in a new domain.
3. The single-condition result that matters for Collin's original question — "can we find the best two-party collaboration strategy" — is: yes, the best strategy in this regime is "agree the frame in advance; reconcile per-turn under attack; don't over-invest in per-turn reconciliation when you're not being attacked." That's a more nuanced answer than "pre-game wins" or "Polis wins"; the regime taxonomy depends on whether you expect adversarial pressure.

Connection to the bridging-paper findings

This pilot tests an unstated extension of the bridging-paper thesis. The bridging paper found that bridging algorithms strengthen relative to majority vote at extreme polarization (P5) and collapse under coordinated adversarial downvoting at moderate polarization (P2). The Catan finding is the dual: per-turn reconciliation aggregators (b and c) strengthen relative to no-coordination under adversarial pressure but don't add much relative value in benign conditions.

Both findings have the same structural shape: aggregation rules that explicitly model cross-party agreement (rather than averaging or majority) gain leverage precisely in conditions where the cross-party signal is meaningful. In the political simulator, that's high polarization. In the Catan setup, that's adversarial counter-coalition. The general claim our work supports — across two different worlds and two different aggregation classes — is that **structured-cross-party aggregation is a regime-specific instrument whose value increases in conditions where the structural property the aggregation rule is built to detect actually exists**. That's a more abstract way of stating the headline thesis we proposed in the bridging paper.

Limitations

The pilot has five worth being explicit about.

The simplified Catan is genuinely simplified. We dropped dev cards, ports, the distance rule (because the 7-hex board has 24 vertices and 8 setup settlements, leaving zero free positions under strict Catan rules; that's an artifact of the board-size choice). The strategic depth of the simplified game is real but smaller than full Catan. Results may not generalize to the full game's combinatorial complexity.

Condition (d) is a stub. The Habermas mediator should be implemented as a real LLM call with private submissions, joint plan generation, and veto-and-fallback semantics from Tessler 2024. The stub produces a flat 20% win rate; that's not informative about what a real mediator would do. This is the most important single follow-on experiment.

The personas are rule-based, not LLM-based. A persona is a parameter triple (risk tolerance, expansion preference, trade openness with adversary), not a deliberating agent. A more sophisticated setup would have the personas themselves be LLM-driven and reason about their own strategy at each turn.

One adversarial geometry. The counter-alliance plays a specific set of four tactics. We have not tested sybil-type attacks (P3/P4 pretending to defect in order to be invited to the alliance), slow-drip noise, or hybrid attacks. The 7-pp adversarial vulnerability of condition (a) is a single point on a larger attack surface.

N=30 games per cell, 720 total. This is a pilot. Confidence intervals on the +9pp deltas span at least ± 5 pp at this sample size. Strong follow-on work would 5 $\times$ or 10 $\times$ the trial count and report bootstrap CIs.

What we'd do next

Three concrete experiments, in order of operator-value:

1. **Replace condition (d)'s stub with a real LLM mediator.** Bakker–Tessler-style: each ally privately submits their preferred plan to a Claude / GPT call that produces a synthesized joint plan with veto-and-fallback. Sweep with the same matrix. The single most important experiment — without it, condition (d) isn't really tested.
2. **Scale to full Catan.** Add dev cards (especially the knight and Largest Army flow), ports, the distance rule on a 19-hex board. Re-run the sweep. Test whether the "coordination strengthens under attack" finding survives the increased strategic complexity.
3. **Vary alliance type.** This pilot's alliance is symmetric (P1 and P2 have equal stake in the joint outcome). Real cooperative deployments often have asymmetric alliances — junior/senior partner, side-deal alliances against a third party. Vary the alliance structure and test which coordination mechanisms are robust to asymmetry.

Total: roughly two to four days of team-cycle time, mostly in Forge's implementation and sweep runtime. We can start any of these on your word.

Appendix: the artifacts you can poke

- **PR branch:** feat/researchy-team-bridging-world-designs on quome-cloud/openworld (also has the bridging-paper experiments)
- **Catan code:** experiments/catan/*.py
- **Design doc:** docs/strategy/catan_world_design.md (Prism)
- **Sweep results:** experiments/catan/results/sweep_results.csv , gap-fraction-like SVG figure
- **Tests:** tests/test_catan_board.py (36 tests) and others in tests/ (88 total pass)

Wall-clock from Collin's "How's it coming?" prompt (M29301, 16:33 UTC) to this note + email: about 1h 15 min. Most of which was Forge's runtime budget on the 720-game sweep. The Catan world implementation itself was 21 minutes across 7 cycles.

Open to follow-on as noted, or to redirect entirely if a different cooperative-game world would be more useful for the underlying research question.
